ABSTRACT

Autonomy is required to support current and future space robotics missions. Planetary exploration robots and unmanned reusable space vehicles will require a high level of autonomy to perform tasks more efficiently.

Over the last 5 years, the Canadian Space Agency has designed, implemented and tested different autonomy techniques on typical autonomous robotics scenarios. The approaches that were tested include Finite State Machines (FSM), Hierarchical Task Networks (HTN) and Goal Decomposition Hierarchies (GDH).

The ARGO Cortex Toolbox merges some of these techniques and allows the implementation of hierarchies of finite state machines. It allows state machines to be designed modularly in order to be reused in different contexts. This feature permits the creation of FSM Libraries. The Cortex Panel provides features to design, manage, generate code, execute, and to monitor execution in real-time or offline. The current release supports Java and code generation. The code generated can then be integrated into the specific framework depending of the application.

1 INTRODUCTION

Over the last few decades, robots have played an increasingly important role in the success of space missions. The Shuttle Remote Manipulator System (also known as Canadarm) on the Space Shuttle has enabled the on-orbit maintenance of precious space assets such as the Hubble Space Telescope. On the International Space Station (ISS), the Canadarm 2 has been a crucial element in all construction activities. Its sibling, Dextre, will be essential to the maintenance of the ISS. In the context of planetary exploration, robotics has also played a central role on most landed missions. The rovers “Spirit” and “Opportunity”, once an interesting geological feature has been identified, it takes three command cycles (of 12 hours each) to go apply an instrument to it [1]. The scientific return on investment is therefore severely limited by the lack of on-board autonomy capability.

Several architectures have been developed to address the issues associated with ground control of space-based robots. However, since the usual mode of operation for space robotics in the past has been tele-operation with direct operator control or supervision, most of the approaches have not focused on the implementation of autonomy. In the late 1990’s, the Canadian Space Agency and their industrial partner, MD Robotics, have developed the Intelligent, Interactive Robotic Operations (IIRO) framework.
ARGO and Ground Operations (Agency has been developing the Autonomous Robotics
missions. CLARAty is object oriented and according to
different vehicles/robots/instruments involved in Mars
provide a systematic framework for treating all the
for many missions. The main goal of CLARAty is to
proprietary architecture that is becoming a requirement
time operation of multiple rovers. CLARAty [8][9] is a
command sequences.

Similar architectures were developed in Europe at the
same time. The Modular Architecture for Robot Control (MARCO) developed by DLR addresses
similar issues in the context of tele-operation and some
aspects of scripted play-back [6]. The MARCO
architecture and its relatives have been used on several
missions including ROTEX and ETS-7. Two other
architectures were also developed under the leadership
of the European Space Agency: FAMOUS and DREAMS also concentrated on the issues associated with the teleoperation of robots in space. In both cases, special attention was dedicated to the issues surrounding planning, verification and execution of command sequences.

Despite the wealth of research in autonomous robotics and in control architectures for space robots, relatively little has been done to address specifically the needs of autonomous space robots. NASA/JPL have been developing/proposing two different architectures for applications with a higher degree of autonomy in the last few years: CAMPOUT and CLARAty. CAMPOUT [7] is a control architecture for the real
time operation of multiple rovers. CLARAty [8][9] is a
proprietary architecture that is becoming a requirement
for many missions. The main goal of CLARAty is to
provide a systematic framework for treating all the
different vehicles/robots/instruments involved in Mars
missions. CLARAty is object oriented and according to
the publications provides a high degree of reusability.

In parallel with these efforts, the Canadian Space
Agency has been developing the Autonomous Robotics
and Ground Operations (ARGO) software suite. ARGO
provides a framework for the integration of the space
operations process from planning to post-flight analysis. The objective of ARGO is to reduce
operational costs and increase efficiency by providing
operator aids and permitting the implementation of a
level of autonomy appropriate to the application.

The target applications of the ARGO framework [10]
cover the full spectrum of autonomy from supervisory
control such as might be expected for ISS robotics to
more autonomous operations such as would be
encountered in planetary exploration missions. It also
covers the full range of space robotic applications from
orbital manipulators to planetary exploration rovers. One of the important features of the ARGO framework
is that it does not provide a universal architecture for
ground control and autonomy. Instead, ARGO
provides a set of toolboxes that can be assembled in a
variety of manners depending on the application and its
requirements. To facilitate the re-use of software, the
design is modular and portable to the maximum extent possible.

Several toolboxes already exist within the ARGO
framework. The central element of the ARGO
framework is the Cortex Toolbox, which provides a set
of tools to implement on-board autonomy software based on the concept of hierarchical finite state
machines. The Cortex Toolbox allows an operator to
graphically generate the behaviours to be implemented
on the remote system. It automatically generates the
code to be uploaded and it can be used to debug and
monitor the execution of the autonomy software on-
line and off-line.

2 CONCEPT OF OPERATION

The basic premise behind the design of ARGO is the integration into a single environment of the operations
process from planning through verification to execution and post-flight analysis. ARGO provides a set of tools that can be connected in context-dependent configurations. For example, to plan and verify
command sequences, the command and telemetry interfaces can be connected to a virtual environment
composed of a simulation model of the system to be
controlled along with a graphical rendering of the
system and its environment. At run-time, the same
command and telemetry interfaces get connected
seamlessly to the real system in space to upload the
pre-verified command scripts. After execution, it is
possible to connect the telemetry interface to the
logged telemetry files to conduct off-line post-flight
analyses.

One key feature of ARGO is the capability to
implement varying levels of autonomy as appropriate
for the target application. This is usually dictated by
the quality of the information being fed back to the
operator. Autonomy is not required when the operator
has adequate, up-to-date information and the ability to intervene in a timely manner. However, if the operator
only receives out-of-date information or loses the
ability to intervene, then he is not capable of making
timely decisions and some amount of local decision-
making capability is required at the remote site. Factors
that can influence the level of autonomy required
include long time delays, low communication
bandwidths, intermittent windows of communication,
poor situational awareness and a dynamic environment.
For example, in the presence of communication links with low latency, high bandwidth and high reliability, it is possible to maintain the operator in the loop for every decision. Primitive commands can be sent to the remote robot one at a time and confirmations can be requested from the operator before any command is executed. In such a case, the operator can intervene and over-ride the robot in case of anomaly.

In contrast, a rover on the surface of another planet is subject to communications with long delays, narrow bandwidth and frequent blackouts. The operator has relatively poor situational awareness because of the bandwidth limitations and no ability to intervene in a timely manner because of the long delays and frequent blackouts. The environment is unstructured and, in some cases, could even be unknown to the operator. In this case, it is preferable to implement some autonomous decision-making capability. Relying on the operator for every decision will result in long idle times between communication windows while the robot is waiting for instructions.

To implement such a variety of levels of autonomy, the ARGO framework makes use of concepts such as command scripts and autonomous behaviours. Command scripts are files in which sequences of commands are recorded for automatic execution. The scripts are built using the finite state machine formalism, which is a convenient powerful way to represent logical rules. Commands are represented as discrete states that are linked by event-driven state transitions. In this context, states represent individual actions to be performed by the robot and transitions are events that cause the script to leave its current state to move into the next one. Typical state transitions can include external events such as sensor values and operator inputs, as well as internal events such as completion of the previous command or failure to complete it. The finite state machine formalism allows the implementation of decision-based branching as well as loops in the script. The simplest incarnation of a command script is a linear series of primitive commands for the robot to execute from start to finish. Autonomous behaviours are built using the same methodology as scripts. In fact, behaviours can be seen as sub-scripts that can be invoked to handle some predefined conditions that the robot is expected to face during its mission. Whereas scripts are specific to one particular scenario, behaviours are libraries of action sequences to be undertaken by the robot under triggering conditions. Behaviours, therefore, provide the robot with some amount of reactive autonomy to make decision and take action on a determined set of events or conditions.

Behaviours can be hierarchical in nature: i.e. the states in the finite state machine representing a behaviour can themselves be behaviours. Behaviours provide the capability for operators to generate much more compact command scripts since complex operation sequences can be encapsulated in a single command that can be invoked at different times in a script or even by another behaviour.

The fact that ARGO treats behaviours in the same manner as command scripts allows the operator to program, verify and uplink autonomous behaviours in the same development environment that is used for operations planning. Thus, ARGO truly provides an integrated environment for all operations-related issues from design and testing of autonomous behaviours to planning, verification and execution of command scripts.

3 THE CORTEX TOOLBOX

The central element of the ARGO framework is the Cortex Toolbox, which is used to implement command scripts and sets of reactive behaviours. Cortex has been developed in light of the fact that the development of such behaviour sets rapidly becomes labour intensive even for relatively simple systems when using low level programming languages, thus making reusability very difficult if not impossible. Cortex is based on the Finite State Machine (FSM) formalism, which provides a higher-level way of creating, modifying, debugging, and monitoring such reactive autonomy engines. Some advantages of this representation are its intuitiveness and ease with which it can be graphically constructed and monitored by human operators.

The concept of hierarchical FSM allows a high-level FSM to invoke a lower-level FSM. This provides the capability to implement hierarchical task decomposition from a high-level task into a sequence of lower-level tasks. If the FSM is implemented in a modular fashion, it allows the implementation of the concept of libraries that provide the operator with the re-use of FSM from one application to another.

In general, FSMs are used to represent a system using a finite number of configurations, called states, defined by the system parameters or its current actions. In the FSM shown in Figure 1, the states are Starting_Motion, Turning, and Stopping_Motion. In this case, actions are defined in state, and they occur during state entry, re-entry and exit. For example, in Figure 1, when entering the Turning state, the current robot azimuth angle could be recorded to serve as a starting point for the destination angle computation.
The system can transition from one state to another based on its current state, conditions and outside events. Conditions on transitions are often referred to as Guards, and are implemented as statements that can be evaluated as being either true or false. Outside events, called Triggers, make the FSM evaluate its transition's guards and enable a transition to occur. In Figure 1, the system will transition from Starting_Motion to Turning once the robot motion is confirmed, or from Turning to Stopping_Motion if the compass is functioning correctly and its readings confirms the robot has turned by the specified angle. In this particular FSM, no specific Triggers have been defined, so any Trigger (such as a periodic "CLOCK" event) will make the FSM evaluate its transitions.

A set of states connected together by transitions forms a state machine. In Figure 1, the block Turn_on_Spot_by_Angle is an FSM that implements a behaviour that has a mobile robot turn on the spot. The FSM also contains parameters it uses to make decisions (such as the current robot heading and the commanded angle of the turn) or on which it acts (the robot itself).

In Figure 1, Starting_Motion is represented as a single state. However the logic to be used in this state could be complex. In order to represent the state logic, the user can decide to use a sub-FSM in its place. The result is a Hierarchical Finite State Machine (HFSM) as shown in Figure 2.

In this case, the Starting_Motion sub-FSM can be made modular by specifying the robot on which it acts as an input parameter. Defining parameters required or produced by a FSM defines its interface to the outside world thus allowing its reuse in various higher levels FSMs, an approach that has been successfully used in software libraries for years. This is the strategy used by Cortex to provide FSM modularity and reusability.

3.1 Cortex Architecture
The architecture provides modules that implement the functionalities of the Cortex framework. Figure 3 shows the two parts of the Cortex architecture. The Development Environment refers to the environment used by the developers to create, design, generate, deploy, control, command and monitor autonomy engines. The Target System Environment refers to the system where the autonomy engine is running. The modules are portable and have been developed with Java. They have been tested on Windows, Linux and Solaris. In addition, ARGO provides Java packages to interface with non-java code (e.g. Simulink, C, C++).

3.2 Graphical User Interface
Cortex modules are all bound into a single Graphical User Interface (GUI). This interface provides all the features required to execute all the steps mentioned in the previous section: It provides panels to
- edit and create Cortex projects;
- generate and compile real-time code;
- deploy the real-time code onto the target system;
- execute, command, control and monitor local and remote instances of the real-time code;
- playback previous state and parameter changes;

The use of an intuitive graphical representation of FSM (see Figure 4 and Figure 5) by Cortex allows the developer/operator to concentrate on the problem to be
solved instead of concentrating on the programming skills to implement the solution.

Figure 4 – Cortex GUI: FSM Editing

Figure 5 – Cortex GUI: FSM Monitoring

FSM are assembled graphically using States, sub-FSM, junctions (a construct used to combine transitions) and transitions. The operator can provide JAVA code snippets for state actions and transition's guard expressions and can define the inputs, local variables, and output parameters of each sub-FSM. The user can also assign a priority to each transition to force the order in which their guards are tested during execution. Constructs from other FSM can also be graphically "cut-and-pasted" to the current FSM to allow for the reuse of existing FSMs.

3.3 Cortex Code Generation

The current implementation of Cortex provides an automatic code generator that produces JAVA source code to implement the FSM defined by the user. The code generator provides FSM topology checking to detect unreachable states and transition loops. A compiler module then compiles the code, report problems, and helps the operator localise errors by highlighting FSM components where code is in errors.

The Cortex Coder generates real-time code mainly composed of conditional logic statements. It is free of threads and performs computation only on trigger invocations. It is self-contained and does not require the Cortex framework to be executed. The developer may decide to take the real-time code and integrate it by hand in his application. The Cortex Coder currently supports Java but its architecture will eventually support C++.

Cortex supports the distribution of autonomy among multiple systems: for example across several robots or throughout a distributed ground control station. A state from a Cortex project may submit a trigger to another Cortex project using the ARGO REMOTE Toolbox. It is also possible for multiple operators to control, command and monitor the same autonomy engine.

4 SAMPLE CASE

The ARGO framework has been applied to a few reference cases typical of space robotics applications. The application described in this paper is a satellite servicing application in Low-Earth orbit. This is representative of most robotic manipulation tasks in Earth orbit where the environment is known and structured but it is dynamic since the satellite to be captured is in free flight. Bandwidth limitations and communication dropouts dominate the quality of the communication link.

The sample application described below is a laboratory implementation of an autonomous satellite capture scenario based using an active vision system. This implementation is performed on the Canadian Space Agency’s (CSA) Automation and Robotics Test-bed (CART) to validate the Cortex Toolbox in preparation for the TECSAS mission [11].

Figure 6- CSA Automation Robotics Testbed

In preparation for TECSAS, the ARGO technologies are being validated in laboratory on the CSA Automation and Robotics Test-bed (CART). This test-bed, shown in Figure 6, is composed of two 7-degrees-of-freedom manipulators. One of the manipulator arms is used to emulate the motion of the client satellite whereas the other emulates the motion of the manipulator on the servicer satellite.
The overall implementation of this OOS demonstration on the CART test-bed is presented in Figure 7. The overall control architecture of the two robotic arms is implemented in Matlab/Simulink. The execution code is automatically generated using the Real-Time Workshop toolbox of Matlab and is compiled and run on a cluster of Pentium IV computers operating under the realtime QNX environment.

Figure 7: Overall implementation of the CART testbed

The Cortex Toolbox is used to implement the behaviours required for the autonomous capture of the client satellite. On TECSAS, the operator will be responsible for the planning and execution of the long-range rendezvous of the two spacecrafts. The autonomy engine will take control when the two spacecraft are distant by a few meters. It will be responsible for performing the final approach of the servicer spacecraft to the client, deploying the manipulator arm and performing the capture of the slow spinning/tumbling client satellite.

Transitions between phases of the operation are triggered by sensory events. The Cortex engine considers anomalies such as the possibility of the client spacecraft to drift out of the capture envelope of the manipulator (through translation or rotation), blinding of the vision sensor or loss of sight, reduction of the safe distance between the two manipulators below an acceptable limit, or failed capture which results in the client satellite to be sent into a tumble mode. Figure 8 presents a Cortex implementation of a typical OOS scenario that would include an autonomous far rendezvous.

5 CONCLUSION

The Canadian Space Agency has developed the Autonomou Robotics and Ground Operations (ARGO) Framework for space robotic operations. The two objectives of ARGO are:

- To streamline the operation cycle by providing an integrated environment for planning, verification, execution and post-flight analysis.
- To reduce operations costs by enhancing the local decision-making capabilities of space robots through the inclusion of local autonomy.

One of the central building blocks of ARGO is the Cortex Toolbox. This toolbox is used to implement autonomy using the concept of hierarchical finite state machines. The fact that ARGO treats autonomous behaviours in the same manner as command scripts allows the operator to program, verify and uplink autonomous behaviours in the same development environment that is used for operations planning. Thus, ARGO truly provides an integrated environment for all operations-related issues from design and testing of autonomous behaviours to planning, verification and execution of command scripts.

A sample application of the Cortex Toolbox to a laboratory demonstration of a satellite-servicing mission is described. This demonstration is performed in preparation for the validation of the ARGO tools for their usage in the TECSAS satellite servicing technology demonstration mission.
