beyond gravity

DynRPAT: A Novel Parametric Analytical Tool to Efficiently Simulate High-Speed or Low-Gravity Locomotion Conditions for Planetary Exploration Rovers

P. Oettershagen*, A. Sager La Ganga, M. Goury du Roslan, C. Lambelet, S. Michaud Beyond Gravity

October 19th, 2023 ASTRA 2023

philipp.oettershagen@beyondgravity.com

Previous work Quasi-static simulation - RPAT

beyond gravity

DynRPAT extends the RPAT [Oett2012] Beyond Gravity's quasi-static rover simulation:

• What is kept:

- → Wheel-soil interaction [Oett2019] (slip from DP, load, sinkage)
- \rightarrow DEM-based terrain modeling
- \rightarrow Full mission post-processing

DynRPAT features a full dynamic rover model which supports:

- Rover acceleration / deceleration with changing wheel loads and slip-sinkage
- Wheel drop phase after a large obstacle (loss of soil contact)
- Long coasting phases, as in micro-g environments

Quasi-static simulation with ExoMars rendered in Unigine.

Motivation Why a simulation and why dynamic?

- Locomotion analysis drives the mission (e.g. landing site, mission targets)
- Modern rovers such as NASA/ESA SFR [Muirhead2020] travel up to 30x faster than ExoMars...

OR

 evolve in low gravity such as DLR MASCOT [Ho2017] or MINERVA-II

 \rightarrow Dynamics needs to be included

3

The Sample Fetch Rover (SFR) in the field.

Motivation State of the art for simulation

Multi body simulation (MBS):

- Highly accurate rover dynamics modelling
- Require comprehensive inputs

But

- Complexity prohibits quick parametric analysis
 - \rightarrow Low simulation speed

Quasi-static simulation:

- Trade-off between accuracy and simplicity / simulation speed
- Efficiently simulate and compare various rover designs
 - → Good for early rover design

But

Cannot support dynamic locomotion

DynRPAT simulation that is computationally efficient and features:

Highly-dynamic rover motion

Motivation

What we propose

- Full 6-DOF rover kinematics
- Newton Euler Equations of Motion
- Accurate wheel-soil interaction

Furthermore, it supports:

- High-quality planetary terrain import
- Statistical mission analysis

P

Dynamic Modelling Approach

Simulation loop design & assumptions

Based on 3 principal models:

- Wheel-soil interaction model
 - → Compute external forces and moments on each wheel
- Equation of motion of the different bodies
 - → Compute acceleration of system
- Kinematic model from acceleration
 Compute the state vector of each sub-system

Assumptions:

- No air friction and no friction at joints (bogies)
- Infinite stiffness of kinematic chain (except wheel and soil)
- Ideal motor step response

Dynamic Modelling Approach Improved dynamic wheel-soil interaction

beyond gravity

Serial double spring + damper system described as:

 $\begin{cases} F_{Reaction} &= F_{R,wheel} = F_{R,soil} \\ u_{tot} &= u_{wheel} + u_{soil} \\ F_{R,wheel} &= k_{wheel} u_{wheel} + \beta_{wheel} \dot{u}_{wheel} \\ F_{R,soil} &= k_{soil} u_{soil} + \beta_{soil} \dot{u}_{soil} \end{cases}$

 $\rightarrow u_{wheel}$ and u_{soil} updated at each timestep given u_{hub}

 $\dot{u}_{wheel} = \frac{-(k_{wheel} + k_{soil})u_{wheel} + k_{soil}u_{tot} + \beta_{soil}\dot{u}_{tot}}{\beta_{wheel} + \beta_{soil}}$

→ solve a differential equation ensuring stability in case of high stiffnesses (lower integration error)

$$u_{\text{wheel}}^{n} = \frac{-(\beta_{\text{wheel}} + \beta_{\text{soil}})\sum_{i=1}^{n-1} c_{i}u_{\text{wheel}}^{i} + \Delta t \ k_{\text{soil}}u_{\text{tot}}^{n} + \beta_{\text{soil}}\sum_{i=1}^{n} c_{i}u_{\text{tot}}^{i}}{(k_{\text{wheel}} + k_{\text{soil}})\Delta t + (\beta_{\text{wheel}} + \beta_{\text{soil}})c_{n}}$$

Dynamic Modelling Approach

beyond gravity

Newton-Euler equations / solver and rover kinematics

Newton-Euler equations:

- Model accurately influence of external forces / torques
- Solved recursively for each part of the system
- Use rover geometry database (relative position, mass, parent parts)

Motion

$$\frac{\sum_{i=0}^{nbParts} (J_{P_i}^T m_i J_{P_i} + J_{R_i}^T I_i J_{R_i}) \overrightarrow{\dot{q}} + \sum_{i=0}^{nbParts} (J_{P_i}^T m_i \dot{J}_{P_i}) \overrightarrow{\dot{q}}}{= \sum_{i=0}^{nbParts} (J_{R_i}^T \overrightarrow{M}_{EXT_i}) + \sum_{i=0}^{nbParts} (J_{P_i}^T \overrightarrow{F}_{EXT_i})} + \sum_{i=0}^{nbParts} (J_{P_i}^T \overrightarrow{F}_{G_i})}$$

External forces

Solver:

- Forward integration
 - \rightarrow Allow real-time simulation with error $O(\Delta t)$
- Beeman's method [Beeman1976]
 - \rightarrow Allow smaller error $O(\Delta t^3)$

Other optimisation:

- Custom Single Instruction Multiple Data (SIMD)
- Adaptive time step based on speed and hub displacement

$$\overrightarrow{\overrightarrow{q}}_{t+1} = \overrightarrow{\overrightarrow{q}}_t + \Delta t \overrightarrow{\overrightarrow{q}}_t$$
$$\overrightarrow{\overrightarrow{q}}_{t+1} = \overrightarrow{\overrightarrow{q}}_t + \Delta t \overrightarrow{\overrightarrow{q}}_t$$

$$\vec{\dot{q}}_{t} = \vec{\dot{q}}_{t-1} + \underbrace{\frac{5}{12}}_{12} \Delta t \vec{\ddot{q}}_{t} + \frac{2}{3} \Delta t \vec{\ddot{q}}_{t-1} - \underbrace{\frac{1}{12}}_{12} \Delta t \vec{\ddot{q}}_{t-2}$$

$$\vec{q}_{t+1} = \vec{q}_{t} + \Delta t \vec{\dot{q}}_{t} + \frac{2}{3} \Delta t^{2} \vec{\ddot{q}}_{t} - \underbrace{\frac{1}{6}}_{6} \Delta t^{2} \vec{\ddot{q}}_{t-1}$$

$$\vec{\dot{q}}_{t+1}^{\text{(predicted)}} = \vec{\dot{q}}_{t} + \frac{3}{2} \Delta t \vec{\ddot{q}}_{t} - \frac{1}{2} \Delta t \vec{\ddot{q}}_{t-1}$$

IVI

Preliminary Results Demo

beyond gravity

Egress from landing platform:

Dynamic Egress ("Crane") testing:

- "skycrane" deployments, e.g. NASA MSL rovers
 - Accelerations, bogie motion and, orientation during free fall
 - Reaction forces and dynamics upon impact into soft or hard soil.

"skycrane" deployment in DynRPAT

Preliminary Results Computational speed

- The quasi-static original RPAT (quasi-static) was ~150x real-time speed during simulations
- DynRPAT with simple Newton Euler forward integration is **5x slower** than real-time
- DynRPAT with the computational speedups (Beeman's method, wheel-soil accurate finite-difference approximation, and SIMD support) is ~8x faster than real-time on typical CPU.

Preliminary Results Wheel drop testing

Comparison with ExoMars LVM rover:

 Wheel drop from different heights and impact on a hard plate equipped with force sensor

 Maximum force and steady state load correlate between simulation and test

Test

Simulation

2.5

3.0

→ Frequency response was not correlated → DynRPAT is not designed for structural modal analysis.

Usability Features Importing realistic features

GeoTIFF terrain import module:

- Feature high-resolution realistic terrains
- Support digital elevation models (DEMs)
- Include an editor to specify the heterogeneous soil types
 → a soil map: ES1/2/3/4

But

High-resolution terrain topography reconstruction with HiRISE can have noisy terrain with missing values

 Especially true around extremes or blocking terrain such as craters

Terrain selected in Oxia Planum for import into DynRPAT

Usability Features

Importing realistic features

Cleaning:

- The algorithm is divided into three steps:
- 1) Outlier detection
 - \rightarrow Apply a Gaussian kernel (70x70) on terrain image
 - → Compute difference between convolved and original image and △>0.7m = outlier
- Interpolation by kriging [Margaret1990]
 - Train a Gaussian process regression (GPR) model on terrain to interpolate outliers and missing values
- 3) Correction of discontinuities from GPR
 - Convolve an averaging kernel (7x7) on boundaries (link heights)

Terrain with missing values.

Terrain cleaning algorithm applied on noisy terrain with missing values.

Usability Features

Mission analysis and visualization

Parametrically tradeoff different missions against each other:

- Estimate instability of lander Egress by retrieving statistics of slope angles
 - → Place lander randomly in realistic terrain
 - → Calculate lander body and ramp angles
 - Assess percentage of lander placement which results in successful Egress

Realistically visualize in real-time simulated rover traverses:

- → Use Unigine 3D engine
- → Rover/lander states transferred via TCP/IP

Retrieved lander and ramp angles after 1'000 placements. Maximum values are indicated.

DynRPAT live simulation of ExoMars (left) and DynRPAT visualization of ExoMars using Unigine 3D (right)

DynRPAT is simulation tool for planetary exploration rover locomotion.

- Initial comparison with ESA ExoMars LVM rover test data show a good agreement with gradeability tests, wheel drop tests, and Egress tests from lander platforms
- DynRPAT features a combination of computational efficiency and medium-accuracy dynamic modeling
- DynRPAT is well suited to support iterative use-cases, such as preliminary design or operations support for future high-speed planetary exploration rovers

beyond gravity

Full correlation with ExoMars test data

 \rightarrow With more step shape obstacles drop tests

Correlation with test data from faster rovers, such as ESA/NASA's SFR

→ Tests were performed at Beyond Gravity's Zurich

Improvement of wheel-soil contact point modeling

→ Unstable behavior of contact point quickly switching between hard soil (e.g. step shape obstacle) and soft soil → affecting drawbar pull

- Given computational speed, mission statistics can be retrieved for Egress and traversability to support locomotion optimization and selection of mission landing site
 - → Random rover placements and related motion paths on realistic HiRISE/MRO terrains
 - Traversability by measuring the percentage of cases where the rover successfully reaches its target
